

Lecture 13. Multi-armed bandits

COMP90051 Statistical Machine Learning

Semester 2, 2018

Lecturer: Ben Rubinstein

THE UNIVERSITY OF
MELBOURNE

Copyright: University of Melbourne

This lecture

- Stochastic multi-armed bandits
 - * Sequential decision making under uncertainty
 - * Simplest explore-vs-exploit setting
 - * (ϵ) -greedy
 - * UCB algorithm

Exploration vs. Exploitation

CC0

Exploration vs. Exploitation

- “Multi-armed bandit” (MAB)
 - * Simplest setting for balancing exploration, exploitation
 - * Same family of ML tasks as reinforcement learning
- Numerous applications
 - * Online advertising
 - * Portfolio selection
 - * Caching in databases
 - * Stochastic search in games (e.g. AlphaGo!)
 - * Adaptive A/B testing
 - *

CC0

Stochastic MAB setting

- Possible actions $\{1, \dots, k\}$ called “**arms**”
 - * Arm i has distribution P_i on bounded **rewards** with mean μ_i
 - In round $t = 1 \dots T$
 - * Play action $i_t \in \{1, \dots, k\}$ (*possibly randomly*)
 - * Receive reward $X_{i_t}(t) \sim P_{i_t}$
 - Goal: minimise cumulative **regret**
 - * $\mu^* T - \sum_{t=1}^T E[X_{i_t}(t)]$
 - ← Expected cumulative reward of bandit
 - ← Best expected cumulative reward with hindsight
- where $\mu^* = \max_i \mu_i$
- * Intuition: Do as well as a rule that is simple but has knowledge of the future

Greedy

- At round t
 - * **Estimate value** of each arm i as average reward observed

$$Q_{t-1}(i) = \begin{cases} \frac{\sum_{s=1}^{t-1} X_i(s) 1[i_s = i]}{\sum_{s=1}^{t-1} 1[i_s = i]}, & \text{if } \sum_{s=1}^{t-1} 1[i_s = i] > 0 \\ Q_0, & \text{otherwise} \end{cases}$$

... some init constant $Q_0(i) = Q_0$ used until arm i has been pulled

- * **Exploit**, baby, exploit!

$$i_t \in \arg \max_{1 \leq i \leq k} Q_{t-1}(i)$$

- * Tie breaking randomly

- What do you expect this to do? Effect of init Q s?

ε -Greedy

- At round t
 - * **Estimate value** of each arm i as average reward observed

$$Q_{t-1}(i) = \begin{cases} \frac{\sum_{s=1}^{t-1} X_i(s) 1[i_s = i]}{\sum_{s=1}^{t-1} 1[i_s = i]}, & \text{if } \sum_{s=1}^{t-1} 1[i_s = i] > 0 \\ Q_0, & \text{otherwise} \end{cases}$$

... some init constant $Q_0(i) = Q_0$ used until arm i has been pulled

- * **Exploit**, baby exploit... probably; or possibly **explore**

$$i_t \sim \begin{cases} \arg \max_{1 \leq i \leq k} Q_{t-1}(i) & \text{w.p. } 1 - \varepsilon \\ \text{Unif}(\{1, \dots, k\}) & \text{w.p. } \varepsilon \end{cases}$$

- * Tie breaking randomly

- Hyperparam. ε controls exploration vs. exploitation

Kicking the tyres

- 10-armed bandit
- Rewards $P_i = \text{Normal}(\mu_i, 1)$ with $\mu_i \sim \text{Normal}(0,1)$
- Play game for 300 rounds
- Repeat 1,000 games, plot average per-round rewards

Kicking the tyres: More rounds

- Greedy increases fast, but levels off at low rewards
- ϵ -Greedy does better long-term by exploring
- 0.01-Greedy initially slow (little explore) but eventually superior to 0.1-Greedy (**exploits after enough exploration**)

Optimistic initialisation improves Greedy

- **Pessimism:** Init Q's below observable rewards → Only try one arm
- **Optimism:** Init Q's above observable rewards → Explore arms once
- Middle-ground init Q → Explore arms at most once

But pure greedy never explores an arm more than once

Limitations of ϵ -Greedy

- While we can improve on basic Greedy with optimistic initialisation and decreasing ϵ ...
- Exploration and exploitation are too “distinct”
 - * Exploration actions completely blind to **promising arms**
 - * **Initialisation trick** only helps with “cold start”
- Exploitation is blind to **confidence** of estimates
- These limitations are serious in practice

(Upper) confidence interval for Q estimates

- **Theorem: Hoeffding's inequality**

- * Let X_1, \dots, X_n be i.i.d. random variables in $[0,1]$ mean μ , denote by \overline{X}_n their sample mean
- * For any $\varepsilon \in (0,1)$ with probability at least $1 - \varepsilon$

$$\mu \leq \overline{X}_n + \sqrt{\frac{\log(1/\varepsilon)}{2n}}$$

- Application to $Q_{t-1}(i)$ estimate – also i.i.d. mean!!
 - * Take $n = N_{t-1}(i) = \sum_{s=1}^{t-1} 1[i_s = i]$ number of i plays
 - * Then $\overline{X}_n = Q_{t-1}(i)$
 - * Critical level $\varepsilon = 1/t$ (Lai & Robbins '85), take $\varepsilon = 1/t^4$

Upper Confidence Bound (UCB) algorithm

- At round t
 - * **Estimate value** of each arm i as average reward observed

$$Q_{t-1}(i) = \begin{cases} \hat{\mu}_{t-1}(i) + \sqrt{\frac{2\log(t)}{N_{t-1}(i)}}, & \text{if } \sum_{s=1}^{t-1} 1[i_s = i] > 0 \\ Q_0, & \text{otherwise} \end{cases}$$

...some constant $Q_0(i) = Q_0$ used until arm i has been pulled; where:

$$N_{t-1}(i) = \sum_{s=1}^{t-1} 1[i_s = i] \quad \hat{\mu}_{t-1}(i) = \frac{\sum_{s=1}^{t-1} X_i(s) 1[i_s = i]}{\sum_{s=1}^{t-1} 1[i_s = i]}$$

- * **“Optimism in the face of uncertainty”**

$$i_t \sim \arg \max_{1 \leq i \leq k} Q_{t-1}(i)$$

...tie breaking randomly

- Addresses several limitations of ε -greedy
- Can “pause” in a bad arm for a while, but eventually find best

Kicking the tyres: How does UCB compare?

- UCB quickly overtakes the ϵ -Greedy approaches

Kicking the tyres: How does UCB compare?

- UCB quickly overtakes the ϵ -Greedy approaches
- Continues to outpace on per round rewards for some time

Kicking the tyres: How does UCB compare?

- UCB quickly overtakes the ϵ -Greedy approaches
- Continues to outpace on per round rewards for some time
- More striking when viewed as mean cumulative rewards

Notes on UCB

- Theoretical **regret bounds**, optimal up to multiplicative constant

- * Grows like $O(\log t)$ i.e. averaged regret goes to zero!

- Tunable **$\rho > 0$** exploration hyperparam. replaces “2”

$$Q_{t-1}(i) = \begin{cases} \hat{\mu}_{t-1}(i) + \sqrt{\frac{\rho \log(t)}{N_{t-1}(i)}}, & \text{if } \sum_{s=1}^{t-1} 1[i_s = i] > 0 \\ Q_0, & \text{otherwise} \end{cases}$$

- * Captures different ε rates & bounded rewards outside $[0,1]$

- Many variations e.g. different confidence bounds
- Basis for Monte Carlo Tree Search used in AlphaGo!

This lecture

- Stochastic multi-armed bandits
 - * Sequential decision making under uncertainty
 - * Simplest explore-vs-exploit setting
 - * (ε) -greedy, UCB
- Many applications, variations:
 - * Adversarial MAB: rewards not stochastic, but *anything*
 - * Contextual bandits: act based on context feature vector
 - * Reinforcement learning: more general setting
- Workshops week #8: ensembles
- Next lectures: unsupervised learning
